Abstract

In recent years, large transformer-based video encoder models have greatly advanced state-of-the-art performance on video classification tasks. However, these large models typically process videos by averaging embedding outputs from multiple clips over time to produce fixed-length representations. This approach fails to account for a variety of time-related features, such as variable video durations, chronological order of events, and temporal variance in feature significance. While methods for temporal modeling do exist, they often require significant architectural changes and expensive retraining, making them impractical for off-the-shelf, fine-tuned large encoders. To overcome these limitations, we propose *DejaVid*, an encoder-agnostic method that enhances model performance without the need for retraining or altering the architecture. Our framework converts a video into a variable-length temporal sequence of embeddings (TSE). A TSE naturally preserves temporal order and accommodates variable video durations. We then learn per-timestep, per-feature weights over the encoded TSE frames, allowing us to account for variations in feature importance over time. We introduce a new neural network architecture inspired by traditional time series alignment algorithms for this learning task. Our evaluation demonstrates that *DejaVid* substantially improves the performance of a state-of-the-art large encoder, achieving leading Top-1 accuracy of 77.2% on *Something-Something V2*, 89.1% on *Kinetics-400*, and 88.6% on *HMDB51*, while adding fewer than 1.8% additional learnable parameters and requiring less than 3 hours of training time. Our code is available at <https://github.com/darrylho/DejaVid>.

1. Introduction

Video action recognition has seen remarkable progress with the rise of transformer-based video models [2, 7, 10]. To improve their performance, one of the most straightforward and effective approaches is to upscale the model and training data [33]. As such, the leaderboards of major action recognition benchmarks have come to be dom-

Figure 1. **DejaVid system diagram.** We first transform a video into a variable-length temporal sequence of embeddings (TSE) then use Dynamic Time Warping Barycenter Averaging (DBA) [21] to calculate a reasonably “average” TSE per class for its centroid initialization. We then learn per-timestep, per-feature weights for the encoded TSE frames, enabling us to accommodate variations in feature importance over time, as well as finetune the centroid TSE for each output class. For this task, we introduce a new neural network architecture inspired by traditional time series alignment algorithms. In testing, we freeze the post-training centroids and weights and use the same pre-training pipeline to generate TSEs to feed into *DejaVid* for predictions.

inated by 100M–1B+ parameter large video transformers [14, 16, 18, 22, 28–30].

These large encoders process videos with fixed frame counts, heights, and widths, generating a single embedding. On datasets with varying durations, the common approach is to pass multiple temporal clips and spatial crops through the encoder and then average the resulting logits for class prediction [22, 28–30]. However, while the height and width of videos in a dataset are usually constant, their duration can vary significantly [14]. Furthermore, temporal order is far more critical. Unlike image flipping [17], reversing time can alter semantics, such as opening vs. closing a door. When averaging logits from different temporal clips, sequential information in these clips is lost. Moreover, the significance of each feature within a video can change over time. For example, in a basketball three-point shot, early frames emphasize player position, while later frames focus on whether the ball goes in. Although encoders might not explicitly model semantically interpretable features like these, temporal variation in feature importance can also occur for arbitrary features, which mean-pooling fails to capture adequately. This motivates a key observation of our work: by failing to carefully account for temporal dimensions, state-of-the-art large models leave significant accuracy gains on the table.

Improving the temporal performance of large encoders is not trivial. Existing temporal-focused methods require invasive changes to the model, such as inserting temporal-specific layers between transformer blocks [27, 31] or creating model duplications to focus on different input views [11, 32]. These approaches are costly to apply to off-the-shelf pre-trained encoders because they require extensive changes in implementation and costly re-training.

These insights motivate DeJaVid, a lightweight encoder-agnostic temporal approach that substantially boosts model classification performance. The simple yet crucial idea behind DeJaVid is that a video is more effectively represented as a temporal sequence of embeddings (TSE) rather than as a single embedding. This representation naturally preserves chronological order while supporting varying time lengths, addressing the aforementioned shortcomings. DeJaVid is naturally able to use any pre-trained model by consuming a sliding-window of encoded video to generate a TSE, without requiring changes to the model’s architecture, retraining, or fine-tuning. DeJaVid is inspired by the well-known Dynamic Time Warping (DTW) algorithm [4], which dynamically aligns similar data points between two temporal sequences while maintaining their chronological order. In particular, DeJaVid introduces a novel neural network architecture inspired by DTW but with learned per-timestep, per-feature weights to handle the temporal variance of feature importance. Additionally, we develop a custom high-performance CUDA kernel for efficient computation and backpropagation of the (time-weighted) warping distance that outperforms a naive DTW-based implementation by 2

orders of magnitude.

We evaluate DeJaVid by layering it on top of the largest (ViT-g) variant of VideoMAE V2 [28] (abbr. VideoMAE V2-g) as the backbone encoder to evaluate DeJaVid on three popular action recognition datasets: Kinetics-400 [16], Something-Something V2 [14], and HMDB51 [18]. We show that DeJaVid significantly improves on the strongest VideoMAE V2-g baseline, thereby achieving new state-of-the-art performance. In particular, DeJaVid achieves Top-1 accuracy of 77.2% on Something-Something V2, 89.1% on Kinetics-400, and 88.6% on HMDB51, while adding fewer than 1.8% additional learnable parameters and requiring less than 3 hours of training time. We also show that our proposed modifications to DTW, including the temporal weights, can further improve prediction performance.

2. Related Work

State-of-the-Art in Action Recognition. Major action recognition benchmarks are topped by massive video transformers with hundreds of millions or billions of parameters. As of the time of writing, according to Papers with Code, the top performers on Kinetics-400 and Something-Something V2 with verifiable parameter counts have between 600M and 6B parameters [14, 16, 22, 28–30]. However, their evaluations on these two datasets all apply spatial and temporal mean-pooling to the logits at the end, which suffers from the time-related shortfalls related to variable video durations, chronological order of events, and temporal variance in feature significance, as described in Sec. 1.

Temporal-focused Methods for Action Recognition. There have been various works on improving the temporal modeling capability of video transformers. One general approach is to introduce temporal-specific layers in between transformer blocks. For example, ILA employs a mask-based layer that predicts interactive points between frame pairs to implicitly align features [27], ATM applies basic arithmetic operations to pairs-of-frame features between ViT blocks [31], and TAM inserts an attention-based temporal adaptive module between 2D convolutions within a ResNet block [19]. Another line of work is to fuse multiple temporal views in different ways. For example, SlowFast networks feed two different frame rates of a video into separate encoders and add lateral connections between them to fuse information across views [11], and MTV deploys a similar idea but for both spatial and temporal dimensions [32]. However, their performance is not competitive against the aforementioned large state-of-the-art models, partly due to their smaller size. Implementing these methods within the large models would involve considerable implementation changes and expensive retraining.

Learning Temporal Sequence Alignments. DTW is one of the most classic methods for calculating similarities between univariate time series or multivariate ones like our

TSEs [4, 23]. Its traditional formulation is a dynamic programming scheme, but recent work has explored making it differentiable and then applying it to various fields. Soft-DTW [9] shows that DTW makes a good loss function when the min operator is replaced with soft-min. DTWnet [5] proposes using DTW learning for time series feature extraction, and D3TW, OTAM, and FTCL [6, 8, 12] similarly do this for weakly-supervised and few-shot video understanding. While these works have some similarities to our DTW-based temporal representation learning, our method is technically different and superior in three ways:

1. DeJaVid models and learns the temporal variance in feature importance, which none of the other methods do. While classical DTW typically only works for a few dimensions (10-100) that require handcrafting or hand-picking [3], by adding learned weights, we extend DTW to high-dimensional use cases (1000-10000+) like video recognition by letting it learn the important dimensions.
2. We reformulate our DTW-inspired temporal learning algorithm as a new neural network architecture that boosts parallelizability and facilitates differentiability.
3. We introduce changes to DTW to improve model stability, including removing the diagonal transition of DTW.

3. Method

As described in Sec. 1, we represent a video as a temporal sequence of embeddings (TSE). In this section, we assume all videos have been converted into TSEs, and operate in this TSE space. DeJaVid feeds a video encoder a sliding-window stream of frames of an input video to generate a TSE, so the shape of a TSE is $T \times N_f$, where each index along T represents the encoding of a window of frames, and thus T can vary depending on individual video duration. N_f is the size of the embedding vector of the backbone encoder and is constant.

Our problem is to classify TSEs. Specifically, we are given a training set of TSEs with class labels among N_c classes, and our goal is to predict the classes of our validation TSEs. We solve this problem in three broad steps:

1. For each class, we calculate a centroid TSE from the training TSEs of that class.
2. We optimize the centroid TSEs according to some loss function w.r.t. the training TSEs.
3. For each validation TSE, we calculate which class’s centroid TSE is the most similar to it.

Here, Steps 1 and 3 require a definition of distance (or similarity) between TSE pairs, and Step 2 requires the distance metric to be backpropagateable. The following Secs. 3.1 and 3.2 describe how we solve these two problems.

3.1. Definitions

There are multiple ways in which one can define the distance between two TSEs [4, 24], but in this paper, we focus

on a standard time series distance metric: Dynamic Time Warping (DTW), as given in Algorithm 1 (without the red text). DTW aligns two sequences that vary in time or speed by minimizing the distance between corresponding points. The two sequences are aligned by aligning each timestep in the first sequence to one or more consecutive timesteps in the second sequence while maintaining a monotonic relationship where a later timestep in the first must map to a later interval in the second. Monotonicity is maintained in Line 5 of Algorithm 1, where each step only moves forward in time for either sequence (from $i-1$ to i or $j-1$ to j). This alignment minimizes cumulative distance and is commonly visualized as a “warping path” on a 2D grid, which shows the optimal alignment of the two sequences, each depicted in one grid axis.

Algorithm 1 The Standard DTW Algorithm (without diagonal transition) vs. the Time-Weighted DTW Algorithm (red)

Input: Two TSEs $a, b \in \mathbb{R}^{n \times N_f}, \mathbb{R}^{m \times N_f}$; a distance function $dist_w; u \in \mathbb{R}_{>0}^{n \times N_f}$ **temporal feature weights of a**
Output: Distance between a and b

```

1:  $D \leftarrow \text{array}[n, m]$  {Out-of-bounds access returns  $+\infty$ }
2:  $D_{0,0} \leftarrow dist_w(u_0, a_0, b_0)$ 
3: for  $i$  in  $[0, n-1]$  do
4:   for  $j$  in  $([0, m-1]$  if  $i > 0$  else  $[1, m-1])$  do
5:      $D_{i,j} \leftarrow \min(D_{i-1,j}, D_{i,j-1}) + dist_w(u_i, a_i, b_j)$ 
6:   end for
7: end for
8: return  $D_{n-1, m-1}$ 

```

In the standard Algorithm 1, we use the Manhattan distance for the pointwise distance function $dist$. Also, although the original DTW algorithm includes a diagonal transition $D_{i-1, j-1}$ in the min clause, we omit this in DeJaVid because it improves model stability. We discuss this decision in more detail in Sec. 3.4.

Let $D_v(a, b)$ denote the DTW distance between TSEs a and b as returned by the standard Algorithm 1, and let $C \in \mathbb{R}^{N_c \times T_c \times N_f}$ represent the centroid TSEs for the N_c classes. Intuitively, we want to assign each TSE to the class it is nearest to in the DTW space. To do this, we define the predicted probability distribution $\hat{y}_v$ for a training or validation TSE $m \in \mathbb{R}^{T_m \times N_f}$ ¹, and the loss $\mathcal{L}_v$ for m under centroids C and one-hot ground truth vector y :

$$\hat{y}_v(C, m) := \underset{0 \leq i < N_c}{\text{softmin}}(D_v(C_i, m))$$

$$\mathcal{L}_v(C, m) := \text{CrossEntropy}(y, \hat{y}_v(C, m))$$

However, as described in Sec. 1, we observe that the importance of each feature of a video can vary as time progresses. This observation motivates our time-weighted

¹In practice, we perform a LayerNorm operation before the soft-min, but this doesn’t qualitatively change our approach.

DTW distance metric, given in Algorithm 1 with modifications shown in red. The difference is the additional weight input u , which denotes the change in feature importance over time for a . We also modify the pointwise Manhattan distance function to incorporate u : $dist_w(u_i, a_i, b_j) := \sum_{k=0}^{N_f-1} u_{i,k} |a_{i,k} - b_{j,k}|$. The changes are colored in Lines 2 and 5 of Algorithm 1. Intuitively, when Algorithm 1 calculates the distance between two sequences, our time-weighted modification allows it to weight some timesteps more than some other timesteps in the first series, and different features can have different weights as well. Let $D_w(u, a, b)$ denote the time-weighted DTW distance between TSEs a and b as returned by the time-weighted Algorithm 1. We aim to learn the temporal variance of feature importance of the centroids C , so we define $U \in \mathbb{R}_{>0}^{N_c \times T_c \times N_f}$ of the same shape as C to be the time-varying feature weights. To maintain the positivity of distances, we constrain U to be positive. The time-weighted variant of predicted probability distribution $\hat{y}_w$ and loss $\mathcal{L}_w$ are defined similarly as before¹:

$$\hat{y}_w(U, C, m) := \underset{0 \leq i < N_c}{\text{softmax}}(D_w(U_i, C_i, m))$$

$$\mathcal{L}_w(u, C, m) := \text{CrossEntropy}(\mathbf{y}, \hat{y}_w(u, C, m))$$

From now on, we focus on the time-weighted Algorithm 1, since one can set $U = \mathbf{1}_{N_c \times T_c \times N_f}$ to recover standard DTW in Algorithm 1.

3.2. Parallelizability & Differentiability

Figure 2. 1. Each cell of the DTW 2D grid executes a *min* operation and then an *add-dist* operation. Checkmarks show completed cells in row-major order. 2. In diagonal order, a diagonal can be executed as soon as the previous diagonal has finished. Checkmarks show completed cells in diagonal order. 3. We can view each diagonal as a min-pooling layer with kernel size 2 and stride 1, followed by an additive skip-connection layer. 4. We reformulate the algorithm into a serial stack of min-pooling layers interlaced with additive skip-connections.

Algorithm 2 given an equivalent neural-network formulation for Algorithm 1; this formulation facilitates the use of backpropagation for optimizing weights and enhances parallelizability. Before providing the details of the algorithm, we provide some intuition as to how and why it works.

Fig. 2 depicts the 2D grid commonly used for representing DTW warping path(s) between two sequences, as described in Sec. 3.1. We visualize each operation in the nested loop in Algorithm 1 onto the corresponding cell in the grid. We can see that each cell executes a *min* operation on the outputs of its left-adjacent and bottom-adjacent cells, followed by an addition of some pointwise weighted distance $dist_w$. Note that cells are executed in a row-major order in Algorithm 1. Therefore, the critical path length is quadratic ($O(nm)$).

However, we leverage a critical property of Algorithm 1 that enables a reformulation of the algorithm, which is that **each cell can be executed as soon as its left and bottom neighbors have finished**. Therefore, we reformulate Algorithm 1 to execute in **diagonal order** and observe that **the l -th diagonal can be executed as soon as the $(l-1)$ -th diagonal has finished**. Here, we define the l -th diagonal to be the cells $\{(i, j) \mid i + j = l\}$. For example, the top-right of Fig. 2 shows the 4th diagonal. Furthermore, elements in the same diagonal are **mutually independent**, so the work within each diagonal is parallelized. So we have reduced the critical path length to the number of diagonals, obtaining the linear runtime $O(n + m)$.

Because each cell executes at Line 5 of Algorithm 1 a *min* operation on two consecutive cells of the previous diagonal and then adds some $dist_w$ term, we can express the new formulation as a neural net where each diagonal is a min-pooling layer with kernel size 2 and stride 1 followed by an additive skip-connection layer. Each min-pooling layer is executed after its previous skip-connection and min-pooling are completed. So Algorithm 1 is equivalent to a serial stack of min-pooling layers, with skip-connections interlaced in between. These descriptions are formalized in Algorithm 2, where one can see the execution of the interlaced layers at Lines 10 and 11. For differentiability, we rewrite the time-weighted DTW distance D_w as:

$$D_w := SC_{n+m-2} + MP_{n+m-2}(SC_{n+m-3} + MP_{n+m-3}(\dots + SC_1 + MP_1(SC_0) \dots))$$

where MP_l and SC_l are the l -th min-pooling and skip-connection as show in Algorithm 2. Because both min-pooling and additive skip-connections are standard neural network operations, loss gradients trivially propagate through them. In a nutshell, the loss backpropagates to only the $dist_w(u_i, a_i, b_j)$ functions on the optimal warping path, which enables gradient-based optimization on U and C . We leave the detailed formulas for loss gradients $\frac{\partial \mathcal{L}_w}{\partial C}$ and $\frac{\partial \mathcal{L}_w}{\partial U}$ in Supplementary Material.

3.3. System Overview

With the definitions introduced in Secs. 3.1 and 3.2, we now formalize the 3-step solution outlined at the start of Sec. 3. Fig. 1 provides an overview of the DejaVid system. The video encoder takes as input a video clip of fixed duration

Algorithm 2 Time-Weighted DTW Neural Network

Input: Two TSEs $a, b \in \mathbb{R}^{n \times N_f}, \mathbb{R}^{m \times N_f}$; a distance function $dist_w$; $u \in \mathbb{R}_{>0}^{n \times N_f}$ temporal feature weights of a

Output: Distance between a and b

```
1: {Out-of-bounds access to  $D$  or  $SC$  returns  $+\infty$ }
2:  $SC_{0,0} \leftarrow dist_w(u_0, a_0, b_0)$  {The 0-th skip-connection}
3:  $D_{0,0} \leftarrow SC_{0,0}$ 
4: for  $l$  in  $[1, n + m - 2]$  do
5:   {The  $l$ -th diagonal}
6:    $start, end \leftarrow \max(0, l - m + 1), \min(n - 1, l)$ 
7:    $SC_l \leftarrow [dist_w(u_t, a_t, b_{l-t})]_{t=start}^{end}$ 
8:    $D_l \leftarrow \text{array}[end - start + 1]$ 
9:    $kernel, stride \leftarrow 2, 1$ 
10:  for  $i$  in  $\text{range}(0, end - start + 1, stride)$  do
11:     $D_{l,i} \leftarrow SC_{l,i} + \min_{s=0}^{kernel-1} (D_{l-1,i-s})$ 
12:  end for
13: end for
14: return  $D_{n+m-2,0}$ 
```

and outputs an embedding $e \in \mathbb{R}^{N_f}$. Given any off-the-shelf video encoder, we apply a sliding window over each video to produce a sequence of clips, which we then feed into the encoder to produce a temporal sequence of embeddings $E = \{e_0, e_1, \dots, e_{T-1}\} \in \mathbb{R}^{T \times N_f}$, which forms a TSE for each video sample in the dataset. Then, we produce a centroid TSE of shape $T_c \times N_f$ ² for each class by feeding the training TSEs to the DBA (Dynamic Time Warping Barycenter Averaging) [21] algorithm, which calculates a reasonable “average” time series of the inputs while accounting for imperfect temporal alignment. Intuitively, each centroid TSE represents how the class-wide average of the N_f features changes over time. Ultimately, we obtain many training TSEs, each with shape $T \times N_f$ for some varying T , and a stack of centroid TSEs C of shape $N_c \times T_c \times N_f$, where N_c is the number of classes. This concludes the pre-training stage of DejaVid.

In the training phase, to account for temporal variance in feature importance over time, each centroid TSE is paired with a positive weight tensor of the same shape $T_c \times N_f$ that represents the importance of each feature over time. The positivity is to maintain that the pointwise distance $dist_w$ is always positive. We denote the stack of weight TSEs U , with shape $N_c \times T_c \times N_f$. At initialization, the weight TSEs are either filled with ones or random positive values.

In each epoch, we calculate the weighted DTW distance D_w from each training TSE $m \in \mathbb{R}^{T \times N_f}$ to every centroid TSE to get the logit vector $\mathbf{z} = \{D_w(U_i, C_i, m)\}_{i=0}^{N_c-1} \in \mathbb{R}^{N_c}$, on which we apply softmax to get the class prediction $\hat{\mathbf{y}}$ and cross-entropy loss $\mathcal{L}_w$ w.r.t. the ground truth $\mathbf{y}$. The

²We set $T_c = 8$ for all experiments in this work.

weights U and centroids C TSEs are updated during back-propagation. To accelerate forward and backward passes, we implement a custom DTW CUDA kernel that efficiently calculates a slope tensor $S \in \mathbb{R}^{N_c \times T_c \times N_f}$ and an intercept tensor $B \in \mathbb{R}^{N_c \times T_c \times N_f}$ such that $\text{torch.sum}(U \odot (C \odot S + B), \text{dim}=(2, -1))$ equals the logit vector $\mathbf{z}$ and the effective gradients w.r.t. U and C equals $\frac{\partial \mathcal{L}_w}{\partial U}$ and $\frac{\partial \mathcal{L}_w}{\partial C}$. The implementation of the CUDA kernel, roughly speaking, leverages the fact that a weighted DTW distance is essentially the sum of many terms of $u \cdot |c - b|$, which equals $u \cdot (c \cdot (\pm 1) + (\mp 1)b)$, where the (± 1) term contributes to slope S and $(\mp 1)b$ to intercept B .

3.4. Modifications to Standard DTW

As mentioned in Sec. 3.1, unlike the original DTW algorithm, we exclude the diagonal transitions (i.e., transitioning from $D_{i-1,j-1}$ to $D_{i,j}$ in Algorithm 1) for DejaVid. The reason is due to model stability. When matching two series of length n and m , by disallowing diagonal transitions, the warping path from $D_{0,0}$ to $D_{n-1,m-1}$ always takes $n + m - 1$ steps, and so the DTW distance will always be the sum of $n + m - 1$ step-wise distances. If diagonal transitions are allowed, the number of step-wise distances on the warping path can vary, destabilizing the model. Although beyond the scope of this paper, we note that there could be other ways to deal with diagonal transitions, such as assigning or learning a multiplicative or additive distance bias for diagonal vs. non-diagonal transitions, such as in Move-Split-Merge (MSM) [24], a more modern replacement of DTW that treats diagonal transitions differently from non-diagonal ones.

Another modification we made is to fix epoch centroids and weights. That is, at the beginning of an epoch, we make a frozen copy of the current centroids and weights, and then during the epoch, use them to calculate the warping path for each centroid-training TSE pair. Then, along the path, we calculate the pointwise distance using the (non-frozen) originals and perform backpropagation on them. Note that the frozen copies are not updated per batch but instead per epoch. The reason for this modification is again due to model stability. We found that if the warping path calculation mechanism is updated every batch, the distances become noisier from batch to batch, and the model has a harder time converging.

We discuss the effect of these modifications in Sec. 4.4.

4. Evaluation

In this section, we describe our implementation and evaluation of DejaVid.

4.1. Datasets and Evaluation Metrics

We test DejaVid on three different popular action recognition datasets: Something-Something V2 [14], Kinetics-400 [16], and HMDB51 [18]. The first two are large-scale datasets: Something-Something V2 has 168,913 videos for

training and 24,777 for validation, while Kinetics-400 has 240,436 training and 19,787 validation videos. In contrast, HMDB51 only has 3,570 training and 1,530 validation videos, but its smaller size can help us study the model’s performance when the training set is smaller.

Something-Something V2 has 174 action classes that are object and motion-centric, which requires learning the subtle differences between motions and object interactions. Kinetics-400 covers 400 classes of everyday human actions derived from real-world scenarios on YouTube and can be human-object or human-human interactions. Its videos are also longer than those of Something-Something V2 on average (~ 300 frames vs. ~ 40 frames), which can help differentiate the temporal modeling capabilities between models. HMDB51 has 51 human-dominated action classes, like Kinetics-400, containing some individual and some human-human behaviors.

For all these datasets, we train DejaVid on the training sets and test on the validation sets using the same evaluation protocols as those in VideoMAE V2 [28]. We report the top-1 and top-5 accuracy for every experiment on Something-Something V2 and Kinetics-400. Due to the smaller action set of HMDB51, we only report top-1 for experiments on it.

4.2. Implementation Details

Pre-training. We use the largest (ViT-g) model from VideoMAE V2 [28] (abbr. VideoMAE V2-g) as the video encoder.³ VideoMAE V2-g is the only model we experiment with because it is the only SOTA model⁴ that publishes finetuned weights on large datasets like Kinetics-400 and Something-Something V2, which we cannot afford to finetune ourselves. To show that DejaVid is model-agnostic, we apply the same method to other non-SOTA video encoders in Supplementary Material. The native embedding output length of VideoMAE V2 is 1408, which is then converted into N_c logits for class prediction, so we let $N_f := 1408 + N_c$ denote the length of the entire output of VideoMAE V2-g. For DejaVid, we apply a temporal sliding window across the input video T times to feed into the encoder, resulting in a TSE of shape $T \times N_f$. We then randomly sample some TSEs for each action class to calculate its initial centroid TSE using the DBA algorithm [21]. T can be different across different datasets and within the same dataset. In particular, we use $T = 33$ for Kinetics-400 and HMDB51, and $T = 4|vid|$ for Something-Something V2, where $|vid|$ is the length of an individual video. For a detailed description of our pre-training configuration and the choice of width and stride for the sliding window of each dataset, please refer to the Additional Implementation

³VideoMAE V2 publishes different finetuned weights for Kinetics-400 and Something-Something V2, and the script for finetuning on HMDB51, which we can afford to run thanks to the small dataset size. We use the respective finetuned weights for the pre-training stage of each dataset.

Details section in Supplementary Material.

Training & Testing. The pre-training stage gives us a TSE m for each training or validation video as well as the centroid TSEs C . The weight tensor U is either randomly initialized or one-initialized (i.e., filled with ones). To enforce positivity, we actually store the log of the weights and exponentiate them during forward passes. These log-of-weights are randomly initialized or zero-initialized (i.e., filled with zeros). We use the AdamW optimizer with betas (0.9, 0.999) and no weight decay. The initial learning rate for the log-of-weights is $1e-3$ for both Something-Something V2 and Kinetics-400, and $8e-3$ for HMDB51. The learning rates for the centroid TSEs are one-third of the log-of-weights. We use batch size 48 and train for 36 epochs. We use a cosine scheduler across all 36 epochs. A validation run is performed after every epoch, and we report the top accuracy recorded across all epochs.

4.3. Main Results

This section compares our results with previous other temporal-related and state-of-the-art methods. The main baseline is VideoMAE V2-g, which is a billion-parameter video encoder that is state-of-the-art or near state-of-the-art on all evaluation datasets [14, 16, 18, 28]. We test our method on each dataset with three different settings: random-initialization for the weight TSEs U (denoted as *full learning*; $w\text{-init-rnd}$ in the following charts), one-initialization for U (denoted as *full learning*; $w\text{-init-one}$), and finally one-initialization for U but freezing it throughout (i.e., disallowing `optimizer.step()` to act on U ; denoted as *frozen weights*; $w\text{-init-one}$). Note that the last setting is for experimenting with the unweighted DTW distance as in Algorithm 1, so frozen weights with random initialization don’t make sense.

Results on Kinetics-400. As shown in Tab. 1, our method achieves leading accuracy on Kinetics-400. We improve on the strongest VideoMAE V2-g baseline by 0.7%. DejaVid only requires 5.8M parameters, less than 0.6% of the encoder’s parameter count, to achieve this gain. For comparison, the gain from VideoMAE V1 to VideoMAE V2 uses 380M extra parameters to increase the accuracy by only 0.4%. Note that our results are achieved without re-finetuning the encoder, so the training cost is minimal compared to training the encoder. In short, DejaVid is a comparatively tiny add-on that significantly boosts the performance of an off-the-shelf frozen model.

The performance gain of DejaVid is not only due to temporal supersampling. We test this by averaging the temporal dimension of each sample TSE to get a length- $(1408 + N_c)$ vector and using the last N_c elements for class prediction; the result is shown as VideoMAE V2 (temporal supersampling) Tab. 1. When compared against the original setting at VideoMAE V2 5×3 , we see this alone does not improve

the accuracy. Also, the temporal weight-learning does not provide additional benefits on top of our centroid-finetuning for Kinetics-400. We suspect the reason is that the temporal weights increase the expressivity of our method, so overfitting becomes more likely; one future work is to look into regularization for DejaVid.

Results on HMDB51. The results in Tab. 1 show that our model also achieves state-of-the-art accuracy on the HMDB51. We achieve a 0.5% performance gain against the strongest VideoMAE V2-g baseline. To the best of our knowledge and according to Papers with Code, this is the highest accuracy recorded on the HMDB51 action recognition benchmark to date (as of Nov, 2024). This shows that DejaVid works well in a training data-scarce scenario. We draw similar conclusions to those from Kinetics-400 in parameter efficiency – our parameter count is 1.19M, which is less than 0.12% of that of VideoMAE V2-g – and temporal supersampling alone does not improve performance.

Results on Something-Something V2. Tab. 1 compares our results on Something-Something V2 against other works. We outperform the top VideoMAE V2-g baseline with a performance gain of 0.5%. To the best of our knowledge and according to Papers with Code, DejaVid achieves the highest top-5 accuracy and one of the highest top-1 accuracies on the Something-Something V2 action recognition benchmark to date (as of Nov, 2024).

Progress on Something-Something V2 has slowed in recent years, with top accuracy improving by no more than 0.3% between 2022 and 2024 [20]. Such gains often require massive model scaling; for example, InternVideo2 added over 5 billion parameters for a 0.4% boost [30]. In contrast, DejaVid achieves comparable improvements with just 17.6M parameters—fewer than 1.8% of VideoMAE V2-g. This efficiency highlights the significance of our +0.5% accuracy gain, which equates to more than two years of recent progress [28–30].

However, the performance gain is smaller than on Kinetics-400. One possible reason could be the difference in average video length: ~ 40 for Something-Something V2 and ~ 300 for Kinetics-400. Because Kinetics-400 videos are longer, there may be more temporal information

for DejaVid to capture. Another reason may be that the encoder is trained with variable video durations, as described in Sec. 4.2, so one future work would be to re-finetune the encoder with video clips of constant frame-count and retry our experiments.

4.4. Ablation Studies

Centroid vs. Weight Learning. In Tab. 2, we analyze the impacts of centroid and weight learning of DejaVid by freezing one component at a time and comparing the results. As seen, both frozen-centroid and frozen-weight variants yield meaningful accuracy gains against the VideoMAE V2-g baseline, and so both components are indeed beneficial. The centroid component has a greater performance gain on average across the three datasets, giving +0.43% top-1 accuracy gain vs. 0.25% for the weights, but the weight component seems to be more useful when training data is scarce. As for the training data-rich cases, the weight component seems to be more useful in Something-Something V2 than in Kinetics-400, potentially because we have 4 different feature sets from the different sliding window widths, and these features should naturally have different importance, so the one-initialized weights are further away from the global optimal.

Method	Sth-Sth2		K400		HMDB
	top-1	top-5	top-1	top-5

Diagonal Transition of DTW. Tab. 3 presents a comparison between the best (highest top-1 accuracy⁸) setting of

⁷Estimated by running 3 batches.

⁸In the case of tied top-1 accuracies, we apply the same change to each tied setting and average their resulting accuracies after the change.

⁴We were unable to run InternVideo2 on our machine due to one of its required packages, `flash-attn`, being incompatible with our machine.

⁵The authors of VideoMAE V2 report 77.0 and 95.9 for top-1 and top-5 accuracy, respectively, but we measure only 76.7 and 95.8 using their published weights. We suspect the discrepancy is due to the input video loading mechanism. The official GitHub repo of VideoMAE V2 has inconsistent descriptions about the data preparation for Something-Something V2, but as of the time of writing, the source code assumes each video has been converted to a folder of jpeg images, and VideoMAE V2 loads these jpeg files instead of the source video. But when we do exactly that, the top-1 accuracy measures only 75.7. This is understandable since JPEG uses lossy compression. So we modified the source code to use `opencv2` to directly load each video, which gives 76.7 and 95.8.

⁶The definition of these clips are described in Sec. 4.2.

Table 1. Comparison with the VideoMAE V2-g baseline and other relevant variants, SOTA, or temporal methods on Kinetics-400, Something-Something V2, and HMDB51. All accuracies are reported in percent (%). W.A. = Weights Available. Dashes (-) = N/A.

Tab. 2 for each dataset and the same setting but with diagonal transitions turned on. Enabling diagonal transitions consistently performs worse on all datasets. This justifies our choice of disabling diagonal transitions in DejaVid and verifies the insight behind this choice as described in Sec. 3.4.

Fixed Epoch Centroids & Weights for DTW Learning.

We use Tab. 3 to compare the best setting (highest top-1 accuracy⁸) from Tab. 2 for each dataset with the same setting but disabling fixed epoch centroids & weights, where we do not make frozen copies of the centroids and weights for warping-path determination (shown as FECW off). Again, the inferior performance of this group compared to when FECW is on across all datasets justifies our design for DejaVid, aligning with the reasons detailed in Sec. 3.4 about model stability. However, the gap is less significant than that for the diagonal transition. This suggests there may be room for improvement by tweaking the path-determination mechanism, such as only updating every other epoch instead of each epoch.

Custom CUDA Kernel for Accelerating DTW. Tab. 4 summarizes the runtime per epoch of the best-performing settings on all datasets compared to using a naive Python implementation of DTW. All experiments are conducted on a single node with 8 NVIDIA H100 GPUs. We can see that our custom CUDA kernel provides a speedup between 161x and 750x. The most technically significant speedup comes from reducing the critical path length from quadratic to linear, as discussed in Sec. 3.2. Other factors contributing to the speedup include the Python/C++ speed difference and architecture and locality-aware, LibTorch-native implementation of the CUDA-kernel.

5. Conclusion

We presented DejaVid, an encoder-agnostic method that boosts video classification performance without retraining

the encoder or changing its architecture. Instead of converting a video into a single fixed-length embedding like most state-of-the-art encoders do, we feed a backbone encoder a sliding-window stream of frames to obtain a variable-length temporal sequence of embeddings (TSE), which preserves temporal order and supports variable video durations. We then introduce a novel neural network architecture based on Dynamic Time Warping (DTW) with learnable, per-timestamp feature weights to address temporal variance in feature significance. Our ablation studies compare and justify various design choices and modifications to classical DTW, and our evaluation shows that DejaVid achieves state-of-the-art video classification results on a variety of benchmarks, significantly improves the accuracy of a cutting-edge large encoder, and outperforms other temporal methods. In particular, we achieve leading Top-1 accuracy of 77.2% on Something-Something V2, 89.1% on Kinetics-400, and 88.6% on HMDB51, representing a 0.5-0.7% accuracy gain over VideoMAE V2-g while adding less than 1.8% additional learnable parameters and less than 3 hours of training time.

6. Future Work

In this paper, we selected video classification as the evaluation task due to its foundational role in computer vision [15, 16, 26], its real-world importance [1, 11, 13], and the significant amount of highly competitive research focused on it [2, 11, 19, 22, 25, 27–32]. With that said, we can also see the potential of DejaVid – and of the power of fine-grained temporal alignment learning in general – in action segmentation, video captioning, text-to-video retrieval, and any other tasks that can benefit from detailed temporal modeling.
